Abstract

Background. Cleft lip and palate (CLP) is a genetic and environmental malformation of the face. The resulting interruption of the tissue in the mouth and nasal cavity undoubtedly impair basic physiological functions, which impacts the quality of life (Qol) of such patients.

Objectives. To assess orofacial dysfunction using the Nordic Orofacial Test-Screening (NOT-S) in a group of Polish children with unilateral CLP (UCLP). The following hypotheses were presented: 1) orofacial dysfunction is more common in children with UCLP and 2) patients with UCLP have a worse QoL than the control group.

Material and methods. Seventy children at the age of 7–13 years took part in the study. The inclusion criterion was a diagnosis of UCLP. The control group (non-UCLP) was matched by gender and age to the cleft group. The research used the NOT-S questionnaire.

Results. In the cleft group, there were statistically significantly more disorders of functions, such as breathing, chewing and swallowing, and drooling; in the NOT-S examination, there were more disorders of the face at rest, facial expression and speech in the cleft group. Comparing the NOT-S total scores, it was found that in the cleft group, there a disorder of at least 1 function was statistically significantly more prevalent than in the control group. Likewise, the median results in the cleft group were 3 points higher than in the control group.

Conclusions. Using the NOT-S survey, it was possible to confirm both hypotheses. Orofacial dysfunction is more common in children with UCLP and this contributes to a worse QoL for them than for children without UCLP.

Key words: quality of life, orthodontics, cleft and lip palate, NOT-S questionnaire
Introduction

Cleft lip and palate (CLP) is a genetic and environmental facial malformation. According to WHO data, it occurs once per approx. 1,100 births around the world. Facial deformities include a disruption of soft and hard tissues, and asymmetry. Scientific studies have shown that asymmetry is present not only in the maxilla, but can also apply to the orbital, zygomatic and frontal bones. Dental anomalies among these patients include hypodontia, supernumerary teeth, microdontia, taurodontism, and transposition of teeth, while occlusal disorders are most often cross-bite and class III malocclusion.

There is no doubt that the abovementioned abnormalities affect speech, articulation, chewing, nose function, and facial appearance. In addition, patients with CLP significantly suffer from otitis media. Speech disorders of people with CLP include delayed speech development, articulation disorders and dysphonia. Moreover, in some cases, fluid and food refluxes often occur and swallowing is difficult. However, it should be noted that the negative impact of CLP mainly concerns psychosocial problems.

The amount of research conducted around the world shows that there is an interest in the quality of life (QoL) of patients with CLP. Researchers from Brazil have proven that the effect of CLP on QoL increases with age. Studies conducted in Iran showed that the biggest difference compared to the control group was in difficulty pronouncing words, and that the impact on QoL also concerned the confidentiality of the data of the children.

We conducted a survey among the Polish population to study the QoL of patients with UCLP in comparison with a control group. This is the first study to use the NOT-S questionnaire in Poland.

The following hypotheses were proposed:
1. Orofacial dysfunction is more common in children with UCLP.
2. Patients with UCLP have a worse QoL than the control group.

Material and methods

Material

This study was conducted in full accordance with the World Medical Association Declaration of Helsinki and was approved by the Ethics Committee of the Wroclaw Medical University, Poland.

The cleft group (n = 35) comprised of patients of the Department of Maxillofacial Orthopedics and Orthodontics of the Division of Facial Abnormalities at the Wroclaw Medical University. The inclusion criteria were a diagnosis of UCLP (diagnosis code Q37.1 of the ICD10) and an age of 7–13 years. The exclusion criteria were mental retardation, being under 7 or over 13 years of age, and missing teeth not related to tooth replacement. The age of the cleft group was between 7 and 13 years. Before conducting the study, legal guardians were informed about it and were assured about the confidentiality of the data of the children.

The control group, without a diagnosis of CLP (n = 35) and matched in terms of sex and age to the cleft group, were patients of the Division of Maxillofacial Orthopedics and Orthodontics at the Wroclaw Medical University.

Methods

The study used the NOT-S survey after it was translated into Polish by the researchers. The children were examined by the same trained examiner according to the same protocol. Each survey contained data on age, gender, diagnostic code (ICD-10), examination position, and position of the head when seated. The interview reflected 6 domains: I) sensory function, II) breathing, III) habits, IV) chewing and swallowing, V) drooling, and VI) dryness of the mouth. The examination contains sections: 1) the face at rest and tasks regarding 2) nose breathing, 3) facial expression, 4) masticatory muscle and jaw function, 5) oral motor function, and 6) speech. Each of these domains contains from 1 to 5 components for which the patients’ responses or examination results were recorded: X = yes, 0 = no, or (–) = not assessed. If there was 1 or more X answers in a section, the researchers placed a score of 1 in the domain. The results were recorded at the time the survey was conducted on pre-printed NOT-S forms. The total possible NOT-S score ranges from 0 to 12 points. The higher the score, the more severe the orofacial dysfunction and the worse the QoL.

Statistical analysis

Statistical analysis was performed using STATISTICA v. 13 (StatSoft Inc., Tulsa, USA). For measurable variables, the mean, median (Me), upper and lower quartile, and range of variability (extreme values – minimum (Min) and maximum (Max)) were calculated. The frequency
of occurrence (percent) was calculated for qualitative variables. All quantitative variables were checked with the Shapiro–Wilk test to determine the type of distribution. The qualitative variables between groups (cleft compared to the control) were compared using the two-tailed Fisher’s exact test. The quantitative variables between groups were compared using the Mann–Whitney U test. The level of $\alpha = 0.05$ was used for all comparisons.

### Results

Table 1 presents a comparison of the frequency of a particular function based on the NOT-S between the cleft group ($n = 35$) and the control group ($n = 35$). The 1st part presents the results from the 6 sections assessed with NOT-S interviews: sensory functions, breathing, habits, chewing and swallowing, drooling, and dryness of the mouth. The 2nd part contains the results from the 6 NOT-S examination sections: face at rest, nose breathing, facial expression, masticatory muscle and jaw function, oral motor function, and speech. The 3rd part is the summary of the entire test (NOT-S total score).

In the NOT-S interview, it was observed that disorders of functions such as breathing, drooling, chewing, and swallowing were statistically significantly more prevalent in the cleft group. In the cleft group, breathing disorders were found in almost 46% ($n = 16$) of the study participants, while in the control group, this figure was 11.4% ($n = 4$; $p = 0.003$). Disorders of the next 2 functions were also more common in the cleft group: disorders of chewing and swallowing function were noted in 51.4% ($n = 18$ compared to the control group: 8.6%; $n = 3$; $p < 0.001$), and drooling in 25.7% ($n = 9$ compared to the control group: 2.9%; $n = 1$; $p = 0.013$). In addition, the summaries of the interview part were compared. The number

NOT-S – Nordic Orofacial Test-Screening; 0 – non-affected; 1 – affected; n – number of participants; *two-tailed Fisher’s exact test.
of participants with a disorder of at least 1 function was also listed. There was a disorder of at least 1 function statistically significantly more often in the cleft group than in the control group (94.3% compared to 54.3%; p < 0.001).

In the NOT-S examination, it was observed that in the cleft group, there were statistically significantly more disorders of functions such as face at rest, facial expression and speech. In the cleft group, facial disorders at rest were found in almost 66% (n = 23) of the study participants, while in the control group, it was 11.4% (n = 4; p < 0.001). Disorders of the 2 other functions were also more common in participants from the cleft group. In the cleft group, facial expression disorders occurred in 85.7% (n = 30 compared to the control group: 2.9%; n = 1; p < 0.001) and speech disorders in 71.4% (n = 25 compared to the control group: 8.6%; n = 3; p < 0.001).

In addition, the summary results of the NOT-S examination were also compared. In the cleft group, there were statistically significantly more disorders of at least 1 function than in the control group (100% compared to 22.9%; p < 0.001). Comparing the total score, it was also found that in the cleft group there were statistically significantly more disorders of at least 1 function than in the control group (100% compared to 68.6%; p < 0.001).

A comparison of the results of the NOT-S between the cleft group (n = 35) and the control group (n = 35) is presented in Table 2. The summary of the NOT-S interview results, the NOT-S examination and the NOT-S total score showed statistically significantly higher values in the cleft group than in the control group. In the cleft group, the Me of the NOT-S interview scores was 2 points, the Min was 0 points and the Max was 5 points (compared to the control group: Me = 1 point, Min = 0, Max = 2; p < 0.001). The Me in the NOT-S examination total score was 2 points, (Min = 1, Max = 4; compared to the control group: Me = 0; p < 0.001). Comparing the NOT-S total score, it was also found that Me values in the cleft group were 3 points higher than in the control group (p < 0.001).

Discussion

This is the first study among the Polish population to use the NOT-S questionnaire. The questionnaire was conducted to assess orofacial dysfunction in children with UCLP in comparison with the control group. Both hypotheses have been confirmed.

Disorders in the cleft group mainly concerned breathing, chewing and swallowing, drooling, face at rest, facial expression, and speech. These results are consistent with data published by Hairfield et al.,\(^{18}\) who showed that people with UCLP statistically more often have respiratory problems. This may be directly due to the narrowing of the upper respiratory tract within the nasal cavity among patients with UCLP.\(^ {19}\) However, it is worth emphasizing that the paranasal sinuses remain well-developed.\(^ {20}\) Respiratory plethysmography in combination with an integrated pneumotachograph, to measure the percentage of nasal breathing, and a flow pressure test showed that most people had less than 0.4 cm\(^2\) of airway, which is less than normal.\(^ {21}\)

Chewing and swallowing disorders affect 51.4% of the cleft group (n = 18; compared to the control group: 8.6%; n = 3; p < 0.001). Using a chewable test material, the particle size of the crushed food was determined in patients with UCLP; it was found to be larger in the cleft group than the control group. Likewise, the number of chewing cycles needed to crush the material was greater.\(^ {22}\) It is worth emphasizing that the orbicularis oris muscle tension measured with an electromyograph\(^ {23}\) was higher in the group of patients with UCLP than in the control group while swallowing at rest.

On the other hand, the results regarding dryness of the mouth show that in the group with UCLP the problem was not statistically significantly more frequent. This confirms a study published in 2008,\(^ {24}\) in which sialometers and sialochemistry were used to assess these patients. There were no differences in the abovementioned parameters between patients with UCLP and those in the control group. Interestingly, cortisol\(^ {25}\) concentration in the saliva of UCLP patients was also checked as an expression of stress response to determine health-related quality of life (HRQoL). There was no difference in salivary cortisol levels between the patient and control groups. No correlation between cortisol concentration and HRQoL was confirmed.

In the NOT-S examination, facial disorders at rest affected 66% (n = 23) of patients, while in the control group, this figure was 11.4% (n = 4; p < 0.001). It has been shown that the face of patients with CLP is perceived more

negatively than that of people without the disorder. Moreover, observation of the nose and mouth area in these people lasts longer. It has also been shown that patients with CLP looking at other people with CLP spend more time looking at the nose and less time looking at the eyes than people without CLP. It should also be emphasized that the intensity of asymmetry increases with a maximum smile. Based on scientific reports, presurgical nasal molding improves the esthetics of the nose in patients with unilateral clefts of the lip, alveolus and palate, and distinctly flattens nasal wings.

Patients with CLP undergo surgery due to the lack of tissue continuity. However, despite a significant improvement in facial symmetry after surgery, 4 years after surgery the remaining asymmetry is more visible: the philtrum of the upper lip is deviated toward the scar tissue on the cleft side, and the asymmetry of the nose is significantly worse. The effects of secondary osteotomy were also compared. No significant influence was demonstrated on craniofacial growth in children with UCLP.

Considering the aspects discussed above, it is understandable that they affect the QoL of patients with UCLP, which was confirmed in our study.

**Conclusions**

The NOT-S survey is an effective tool for assessing disorders in patients with UCLP. It has been shown that patients with UCLP have more orofacial dysfunctions and worse QoL compared to the control group. Orofacial function areas and treatment outcomes need to be continually evaluated and monitored.
